Scattered occurrences of Palaeogene sediments are found in North-East Greenland, where they overlie unconformably Cretaceous sediments and are capped by Palaeogene basalts. These sediments have received little attention (Watt 1994), except for relatively recent studies (Nøhr-Hansen & Piasceki 2002; Jolley & Whitham 2004; Larsen et al. 2005; Heilmann-Clausen et al. 2008). As part of an ongoing petroleum geological study that focuses on the Jurassic–Cretaceous succession, the Palaeogene sediments were included to better constrain their age, depositional environment and relation to the basalts. Several localities were investigated on Wollaston Forland, Sabine Ø and Hold with Hope, a few of which are described here (Fig. 1).

Eastern Wollaston Forland and Sabine Ø

Discontinuous outcrops of mostly loose and un-cemented Palaeogene sediments occur in Haredal, eastern Wollaston Forland. A N–S-striking normal fault with 100–125 m of downthrow to the east separates the main outcrop in the southern slope into two blocks. The best exposed succession is situated in the western footwall block, where the succession dips 20° to the SW (Fig. 2). It overlies marine mudstones of Late Albian age (Wigginsiella grandstandica Subzone (V1) of Nøhr-Hansen 1993) in the footwall block and of Early to Middle Campanian age (indicated by the dinocysts Alterbidinium inamidesti and Cerodinium diebelii) in the hanging wall block; however, the contact to the Cretaceous is not exposed. A poorly exposed Palaeogene succession in the northern slope is probably from the hanging wall block; the base of the succession and underlying strata are not exposed.

Haredal, southern slope. Approximately 200 m of Palaeogene sediments are partly exposed in the footwall block, forming two upward-coarsening units overlain by basalts (Fig. 2). The lower unit consists of more than 70 m of dark grey mud overlain by 54 m of fine- to medium-grained sand beds alternating with thinner heteroliths topped by more than 2 m of coarse-grained sand. The succession is of earliest Ypresian age based on the dinocyst Apectodinium augustum (Fig. 3) and the nannofossil Discoaster lenticularis. The palynological assemblage is dominated by reworked material from Upper Jurassic (e.g. Gonyaulacysta jurassica), mid to Upper Cretaceous (e.g. Haplocysta bentecue, Chatangiella spp. and Wodehousea spinata) and lower Paleocene (e.g. Alisocysta margarita). The presence of A. augustum may correlate with the A. augustum (P6b) Subzone described from the central North Sea (Mudge & Bujak 1996) and correlated...
with the Paleocene–Eocene thermal maximum (PETM) which occurred at about 56 Ma and lasted for c. 170 kyr (Harding et al. 2011). The upper, coarser-grained part only yielded two dinocyst species *Cerodinium* sp. and *Areoligera* sp. and no nannofossils.

The upper unit consists of more than 20 m of dark grey silty and sandy mud overlain by slightly heterolithic, fine-grained sand (22 m), fine-grained sand (10 m), conglomerate and pebbly sandstone (8 m) topped by a few metres of sand, mud and carbonaceous mud or coal. The palynologi-
Fig. 3. Images of selected dinocysts (1–7) and nannofossils (8–10): 1: Trithyrodinium evittii. 2A, B: Alisocysta margarita. 3: Thalassiphora delicata. 4: Gen et sp. indet. of Piasecki et al. (1992). 5: Apectodinium augustum. 6: Apectodinium paniculatum. 7: Deflandrea oebisfeldensis. 8: Discoaster gemmeus? 9: Helicosphaera seminulum. 10: Tribrichatius orbiculus.

cal assemblages below the conglomerate are dominated by reworked material of mid – Late Cretaceous age and a few specimens of Paleocene age. The succession is of early Ypresian (Early Eocene) age based on poorly preserved specimens of the dinocysts Apectodinium augustum, Apectodinium paniculatum, Deflandrea oebisfeldensis and the nannofossil Tribrichatius orbiculus (Fig. 3). Samples above the conglomerate yielded a few reworked Upper Cretaceous and Paleocene dinocysts together with a few indeterminate algae and the nannofossil Helicosphaera seminulum (Fig. 3). The latter indicates an age not younger than mid Ypresian for the youngest dated sediments in Haredal; this is compatible with a mid Ypresian radiometric Ar/Ar age of 55.02 ± 0.49 Ma for the oldest lava analysed from Wollaston Forland (L.M. Larsen personal communication 2008).

Haredal northern slope. Approximately 180 m of sediments were studied on the northern slope of Haredal (Fig 1). The lower 40 m consist of dark grey mud with a palynological assemblage dominated by reworked material from mid – Upper Cretaceous strata (e.g. Haplocysta bentae, Chatangiella spp. and Aquapollenites spp.). The presence of Trithyrodinium evittii, Spongodinium delitiiense and a few specimens of Senioniasphaera inornata in the two lowermost samples indicates an Early Paleocene age and may correlate with the lower Danian Trithyrodinium evittii Zone (Fig. 2) established from West Greenland (Nøhr-Hansen et al. 2002). The presence of common Senegalinium iterlaaense and Palaeocystodinium bulliforme in the two overlying samples indicates a mid to late Danian age correlating with the Senegalinium iterlaaense and Palaeocystodinium bulliforme zones (2 and 3 in Fig. 2), whereas the next sample contains a few specimens of the dinocysts Alisocysta margarita and Cerodinium striatum indicating a late Danian/earl Selandian age correlating with the Alisocysta margarita Zone (Nøhr-Hansen et al. 2002: 1 in Fig. 2). The upper 130 m of sand and mud contain very few in situ palynomorphs, however the presence of Apectodinium augustum indicates correlation with the Apectodinium augusum (P6b) Subzone, indicating an ?early Selandian – Thanetian hiatus.

Outer Haredal, Dronning Augusta Dal and Sabine Ø. Palaeogene sediments from the southern slope of the easternmost part of Haredal, on the eastern slope of Dronning Augusta Dal, and on the north-eastern slope of Harebjerg, Sabine Ø were also studied and sampled (Fig 1). The successions all contain the PETM dinocyst marker Apectodinium augustum.

North-eastern Hold with Hope

Langsiden. Interbedded in dark grey mud at Langsiden (Fig 1) occurs an 8 m thick unit with sharp-based, upward fining successions of conglomerate and pebbly sand, up to a few metres thick containing large reworked mudstone clasts. The palynological assemblage from the underlying mud is dominated by a reworked flora of late Maastrichtian age indicated by the presence of Tribilastula wilsonii and Wodehousea octospina. The presence of in situ Trithyrodinium evittii, Spongodinium delitiiense and a few specimens of Senioiasphaera inornata indicates correlation with the lower Danian Trithyrodinium evittii Zone (Nøhr-Hansen et al. 2002). The mudstone clasts yielded a mid Cretaceous flora. The palynomorph assemblage of two samples from the overlying mud is likewise dominated by a reworked Upper Cretaceous flora; however, the lower sample also contains a few specimens of the dinocysts Alisocysta margarita and Cerodinium striatum, indicating correlation with the upper Danian/lower Selandian Alisocysta margarita Zone (Nøhr-Hansen et al. 2002). The presence of Thalassiphora delicata in the upper sample indicates a latest Danian/early Selandian age (Nøhr-Hansen & Piasecki 2002).

East of Fosdalen. Approximately 6 m of loose, white-grey, fine- to medium-grained sand with scattered small clay clasts
overlain by a less than 2 m thick bed of dark grey mud covered by volcanic rocks overlies mid Cretaceous sandy mudstone east of Fosdalen (Fig. 1). The palynological assemblage of the mud bed is dominated by spores and pollen and some reworked dinocysts of mid to Late Cretaceous age. In situ specimens of the dinocyst gen. et sp. indet. of Piasecki et al. (1992; Fig. 3) also occur, suggesting fresh to brackish water. The species is common in wells offshore eastern Canada just above the Apectodinium augustum P6b Subzone (H. Nøhr-Hansen, unpublished data). The occurrence of the species immediately below the basalts may indicate an earliest Ypresian age.

**Discussion**

The new biostratigraphic dating shows that the Palaeogene sediments on Wollaston Forland, Hold with Hope and Sabine Ø comprise Paleocene and earliest Eocene strata with a hiatus that probably spans the major part of the Selandian and Thanetian. The age of the underlying Cretaceous deposits east of the fault in Haredal is Early–Middle Campanian, much younger than the Middle Albian previously described from Wollaston Forland (Nøhr-Hansen 1993). The stratigraphic gap between the Cretaceous and Palaeogene sediments thus decreases towards the basin to the east. The large amount of reworked Cretaceous marine palynomorphs including a Late Maastrichtian flora documents uplift of Cretaceous marine sediments and major erosion during the Early Palaeogene. The ages of the youngest Palaeogene sediments and the oldest flood basalts appear to be almost identical; however, the nature of the contact between the sediments and basalts needs to be further investigated to determine whether the contact is angular, as is suggested in places by a relatively steep dip of the sediments.

Discontinuous conglomerate beds with rounded quartzite pebbles and boulders up to 20 cm, as well as cross-bedded sandstones, terminate the upper unit in Haredal and are interpreted as fluvial channel deposits. The absence of basaltic clasts indicates that deposition occurred prior to the volcanic events. The thin overlying succession with a coaly bed is interpreted as an aggrading coastal plain subject to marine inundations. However, the principal part of the Palaeogene sediments accumulated in a marine environment as indicated by marine dinocysts and the presence of scattered marine trace fossils. Thin, fine-grained sandstone beds with flute casts and a massive lower part overlain by beds with parallel lamination and cross-lamination in outer Haredal indicate deposition from turbidite currents. The sharp-based, fining-upward conglomerate beds and pebbly sand from Langsiden embedded in mud are interpreted as channelised gravity flow deposits. The two upward-coarsening units in Haredal suggest that the Palaeogene sediments mainly accumulated during two major depositional phases. Potential by-pass surfaces are identified at the Cretaceous–Palaeogene boundary, at the top of the lower unit, at the base of the fluvial conglomerates and possibly at the sediment–basalt boundary. Coarse-grained sediments may have been transported toward the basin area to the east along these surfaces.
